1 OVERVIEW

This program was coded as an R script (version 3.5.1) written in RStudio. It uses mortality data from the Society of Actuaries Mortality Tables to simulate a number of whole life single annuity premiums prices for an insurance company and produce projected annual profits. The mortality data is used to create a life table which will calculate the annuity expected present value for given ages. The program will accept user input of a starting age range, maturity age, monthly annuity benefit, interest rate, number of policy holder lifetimes to generate, number of company years to simulate, and an ROI interest rate. Using the life table data and user input, the program will create a simulated number of policy holders' lifetimes with random starting and death ages and their calculated premiums. This program will also simulate a profit for a projected number of years to measure the insurance company's annual profit. Several graphs are produced to help illustrate these calculations and together with the tables are saved in an output folder in the same directory as the R script. The calculations and design of this program were advised by Dr. Chin-Mei Chueh, actuarial science professor and Society of Actuaries council member, and Dr. Donald Davendra, computer science professor.

2 Inputs

The mortality data sets from the Society of Actuaries website contain a column for age and a column for the associated probability of death. It is downloaded as a .csv file and read into a variable, mortality_data, in this program. A user defined file, simulation_input.csv, is edited by the user and read into several other variables. This user input file can handle multiple rows of data if the user would like to test several scenarios.

```
# Read and assign input parameters
for (input_index in 1:length(user_input$age_range_start)) {
    input_age_start = user_input[input_index,1]
    input_age_end = user_input[input_index,2]
    maturity_age = user_input[input_index,3]
    monthly_annuity = user_input[input_index,4]
    interest_rate = user_input[input_index,5]
    iterations = user_input[input_index,6]
    company_years = user_input[input_index,7]
    ROI_interest = user_input[input_index,8]
```

11 }

Listing 1: This for loop starts the main body of the program and will loop for every line in the simulation_input.csv file. This shows the first few lines where each value is extracted from input.csv file into individual variables.

After the user input values are stored (Listing 1), the user-defined interest rate is used to calculate some initial variables (Listing 2). These variables will be used in creating the life table which will ultimately calculate the annuity expected present values that will be necessary for calculating annuity premiums and running the scenarios.

```
1 # Calculated initial variables
2 d = interest_rate / (1 + interest_rate)
3 im = 12 * (((1 + interest_rate) ** (1 / 12)) - 1)
4 dm = 12 * (1 - (1 - d) ** (1 / 12))
5 a12 = (interest_rate * d) / (im * dm)
6 b12 = (interest_rate - im) / (im * dm)
```

Listing 2: Calculating constant variables that will be used in calculations to create the life table.

3 CREATING A LIFE TABLE

After input is read in, a life table is initialized with the age and mortality data (qx) that was read in from the .csv from the Society of Actuaries website (Listing 3). Having the initial age and mortality values is necessary to populate the rest of the table columns.

```
life_table <- data.frame(age, qx)
```

Listing 3: The line to create the life table data frame. The values read in from the mortality data table, age and associated mortality, are used to create the rest of the table.

After the data frame is set a series of calculations is run to set the values for the rest of the table. This life table is created ultimately to calculate values from the insurance (Eq. 1) and annuity (Eq. 2) equations. These values calculate the expected present value of the insurance premium from the starting age.

$$A_x = \sum_{k=0}^{\infty} v^{k+1} \cdot_k | q_x \tag{1}$$

Equation 1. The Whole Life Insurance Expected Present Value Equation

$$\ddot{\mathbf{a}}_x = \sum_{k=0}^{\infty} v^k \cdot_k p_x \tag{2}$$

Equation 2. The Whole Life Annuity Expected Present Value Equation

4 Profit Functions

Functions were created to reuse as the program runs through the simulations and for plotting (Listing 4).

```
# Function for determining Whole Life Net Single Premium Policy Price
2 #
3 # @param in age The input age for beginning the insurance policy
4 # @param mat age The age in which the policy matures
5 # @return A double representing the Net Single Premium that was paid for
     the policy
6 WNS premium <- function (in age, mat age) {
      xEy = (life table $lx [mat age + 1] / life table $lx [in age + 1]) * (1 /
     (1 + interest rate)) ** (mat age - in age)
      return (monthly annuity * 12 * (a12 * ax[mat age + 1] - b12) * xEy)
9
11 # Function for determining the reserve at time unit (year)
12 #
13 # @param in age The input age for beginning the insurance policy
14 # @param time unit The unit of time (year) that describes the age of the
     policy
15 # @return A double representing the reserve value for the policy at that
     unit of time
16 WNS reserve <- function (in age, time unit, mat age) {
      xEy = (life_table lx[mat_age + 1] / life_table lx[in_age + 1]) * (1 / 1)
     (1 + interest_rate)) ** (mat_age - in_age)
      return (monthly annuity * 12 * (a12 * ax[in age + time unit] - b12) *
     xEy)
```

```
19
2.0
21 # Function for determining the profit over time for given interests
22
  # @param interest The input interest rate
  # @return A list of calculated profits
  interests profit <- function(interest){</pre>
      yearly_interest <- c((1 + (interest/12))**12)
26
       f value <- c(fund table fund value [1])
27
      p <- c(fund table $ profit [1])
29
      for (year in 2:nrow(fund table)){
30
         yearly interest \langle -c(yearly interest, (1 + (interest/12))**12)
         f_value \leftarrow c(f_value, (f_value[year - 1] * yearly_interest[year]) -
32
      fund table $ total benefit payout [year])
        p <- c(p, (f value [year] - fund table $total reserve [year]))
33
34
      return (p)
35
36
```

Listing 4: Functions to calculate each policy holder's premium price and reserve value and a function to find profit values for a given interest rate.

The first function, WNS_premium(), will calculate a whole life net single premium for a single policy holder with a unique starting age and maturity age. With known data, this value can be used to check the validity of the calculations that were used to create the life table. To find the premium price, the value xEy is first calculated with Equation 3 and then the \ddot{a} variable is chosen from the life table at maturity age plus 1. These two values are used with the a12 and b12 values (from Listing 2) and the benefit value as input for Equation 4 to calculate the whole net single premium annuity price.

$$xEy = \frac{l_{m+1}}{l_{s+1}} \cdot \left(\frac{1}{(1+i)}\right)^{m-s}$$
 (3)

Equation 3. Equation used to calculate the value xEy needed to calculate the annuity premium price. The variable l is from the l_x column of the life table, m is maturity age, s is policy start age, and i is interest rate.

$$p = b \cdot (a12 \cdot \ddot{\mathbf{a}}_{m+1} - b12) \cdot xEy) \tag{4}$$

Equation 4. Equation used to calculate the whole net single premium for annuity where p is the premium price, b is the annual benefit payout, and m is maturity age. The values for a12 and b12 are obtained using the equations in Listing 2 and the xEy is calculated using Equation 3.

The second function, WNS_reserve(), calculates the reserve value that the company must consider and subtract from their fund value to find their actual profit value at a given time. The calculation for reserve is the same as the calculation used for the premium price except that the \ddot{a} variable is chosen from the life table at the location of policy start age plus the given time (years) (Equation 5).

$$r = b \cdot (a12 \cdot \ddot{\mathbf{a}}_{s+t} - b12) \cdot xEy \tag{5}$$

Equation 5. Equation used to calculate the reserve for annuity at time t, where p is the reserve price, b is the annual benefit payout, and s is the policy start age. The values for a12 and b12 are obtained using the equations in Listing 2 and the xEy is calculated using Equation 3.

The third function, interests_profit(), calculates a profit value at a given interest rate. It uses the data from the fund_table generated in the profit projection simulation in Listing 6. The values of this function are used to generate a 3D surface plot to look at profit over time at different interest rates (Figure 4).

5 SIMULATIONS

With the user-defined input of iterations, this program will generate lifetimes for individual policy holders in a loop (Listing 5). These individuals will have a randomly generated starting age (age they bought the insurance) and death age with a given maturity age to determine the price of the premium and the insurance company's reserve on that individual's life policy. This simulation loop is set up as if every client chose the net single premium option. All data generated by this loop is stored in a data frame called lifetimes. This table stores the starting age, maturity age, death age, policy premium price, and a reserve price for each lifetime. Placeholder columns are set for an isDead column and a benefits paid out column to be used in the profit simulation loop later.

```
for (i in 1: iterations) {
      # Generate random integer starting age
2
      if(input age start >= input age end) {
3
           input age = input age start
      } else {
5
          input age = sample(input age start:input age end, 1)
6
      }
8
      # Pick a random death date based on mortality table
9
      death age = input age
10
      while (death age < length (mortality data mortality) &&
             runif(1, 0.0, 1.0) > mortality data$mortality[death age]) {
12
        death age = death age + 1
13
      }
14
15
      # Add the simulated lifetime to policy table
16
      lifetimes [nrow(lifetimes) + 1,] <- c(input age,
17
                                              maturity age,
18
                                              death_age,
19
                                              WNS premium (input age,
2.0
                                                           maturity age),
                                              WNS reserve (input_age,
22
                                                           0, # time zero
23
                                                           maturity age),
                                                     # benefits paid out
                                              FALSE) # isDead?
    } # End simulate lifetimes
```

Listing 5: The loop to run simulations for user-defined number of iterations. Policy starting age is randomly chosen in the age range between age start and age end and the death age is determined by using the mortality percentage form the life table for each year the policy holder lives. Once the death age and start age is determined, the policy premium price and reserve price can be determined.

The second simulation in this program (Listing 6) determines the annual profits for a user-defined set of years. Number of company years to simulate and the ROI interest rate from the user input file are used. The number of lifetimes generated from the previous loop are used to begin the simulation. This sets the year zero reserve value, fund value, and profit from "selling" these policies.

Once the loop begins, it checks to see each individual policy holder is still alive and if the age of the policy has reached the maturity date yet. If the maturity date is not met and the policy holder is alive, the reserve value is updated. If the maturity date is met and the policy holder is alive, then the reserve value is updated and a benefit payout is calculated for that year. If the policy holder is dead at the given year, then the benefit payout and reserve value is set to zero.

The data generated by this loop is added to a table called fund_table. This table will show year, total reserve, total number of payouts, total benefit payout value, yearly interest rate, fund value, profit value, number of accumulated deaths, and number of unmatured policies. The fund value in a given year is calculated by taking the fund value of the previous year, multiplying it by interest, then subtracting any benefits paid out in the previous year. The profit value is then calculated by taking the fund value of the given year and subtracting the total reserve for the given year.

```
1 # Begin profit simulation loop
2 for (year in 2:(company years + 1)){
     # For each year, calculate the benefit payout value and reserve
     # Also keeps track of number of payouts, total deaths, and unmatured
      policies
     one year payout = 0
     payouts = 0
6
     deaths = 0
7
     unmatured = 0
     for (j in 1:nrow(fund policies)){
9
        matured = (fund policies $StartAge[j] + year - 1 > fund policies $
10
     MatAge[j]) # has the policy matured?
        dead = (fund policies $StartAge[j] + year - 1 > fund policies $DeathAge
            # has the policy holder died?
      [j])
12
        # if not matured and not dead
13
        if(isFALSE(matured) && isFALSE(dead)) {
14
             fund policies $ Reserve[j] = WNS reserve (fund policies $ Start Age [j],
      year - 1, fund policies $MatAge[j])
            unmatured = unmatured + 1
             fund policies $benefit Payout [j] = 0.0
17
         }
18
        # if matured and not dead
20
        else if(isTRUE(matured) && isFALSE(dead)) {
21
             one year payout = 12 * monthly annuity
             fund policies $benefit Payout [j] = one year payout
             fund policies $ Reserve[j] = WNS reserve (fund policies $ Start Age [j],
24
      year - 1, fund policies $MatAge[j])
```

```
payouts = payouts + 1
          }
2.6
27
        # if dead
28
         else if(isTRUE(dead)){
29
             deaths = deaths + 1
30
             fund policies $isDead[j] = TRUE
             fund policies Reserve[j] = 0.0
32
             fund policies $benefit Payout [j] = 0.0
33
         }
     }
35
36
      year num \leftarrow \mathbf{c} (year num, year -1)
37
       total reserve <- c(total reserve, sum(fund policies $Reserve))
      num payouts <- c(num payouts, payouts)
39
       total benefit payout <- c(total benefit payout, sum(fund policies$
40
      benefitPayout))
      yearly ROI \leftarrow c(yearly ROI, (1 + (ROI interest/12))**12)
41
      fund value \leftarrow c (fund value, (fund value [year - 1] * yearly ROI [year]) -
42
       total benefit payout [year - 1])
       profit <- c(profit, (fund value[year] - total reserve[year]))</pre>
      accumulated deaths <- c(accumulated deaths, deaths)
44
      unmatured policies <- c(unmatured policies, unmatured)
45
47 } # End profit simulation loop
```

Listing 6: The for loop for simulating projected profit for a set number of years for the insurance company selling whole single net premium annuities.

6 GRAPHING

Four graphs are generated to illustrate some of the output data: a histogram of death ages generated by the simulated lifetimes loop, monetary values over time, how increasing age with the user-defined maturity age and monthly benefit affects premium prices, and a projected profit value with varying interest rates over time. Sample output graphs can be seen in the Figures 1, 2, 3, and 4.

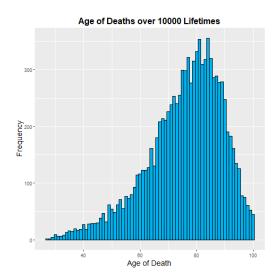

Figure 1: Histogram of deaths at a given age.

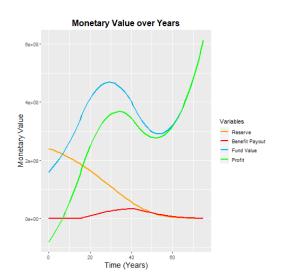

Figure 2: Benefits paid, reserve value, fund value, and profit over a user-defined set of years.

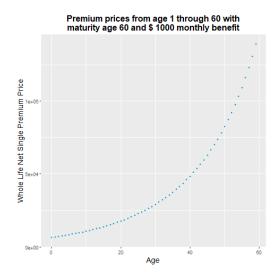

Figure 3: Prices of whole life single net premium at given age range, maturity age, and desired annuity benefit.

Figure 4: Company's projected profit for varying interest rates over a user-defined set of years.

7 FUTURE CONSIDERATIONS

There are a few future considerations for expanding this program. One obvious one would be adding yearly, monthly, and all term policy premiums. As it is, this program calculates only whole net single premiums prices. This would probably take a major overhaul of existing code and make it considerably longer. Another small modification might be to have a single, easy way for a user to test just one policy. This may help if the user wants to give a single client an estimate. A third consideration may be adding another user input file to be able to run several different mortality tables at once to compare to each other. For instance, the client could compare non-smoker mortality data to smoker mortality data. These are just a few ideas however and implementing these considerations or other ideas would be entirely dependant on the client's needs.
